Dynamic Light Scattering Technology. Particle size can be determined by measuring the random changes in the intensity of light scattered from a suspension or solution. This technique is commonly known as dynamic light scattering (DLS), but is also called photon correlation spectroscopy (PCS) and quasi-elastic light scattering (QELS). The latter terms are more common in older literature. After a few comments on the applications of dynamic light scattering, this page explains the technique beginning the actual phenomena under study (particle motion, not particle size). The nature of the measurement Dynamic light scattering is a label-free method that allows for a measure of the hydrodynamic radius of a single species, or the hydrodynamic radius distribution of an ensemble of macromolecules. Fluctuations in the intensity of scattered light, occurring on the timescale of micro- to milliseconds, are analyzed to produce an autocorrelation function that reports on the translational diffusion of the species under study (Inagaki, Ghirlando, & Grisshammer, 2013; Provencher, 1982a, 1982b). The nature of the measurement Dynamic light scattering terms methods, where temporal fluctuations of scattered light are measured. The temporal evolution of the intensity of the scattered light is related to the motion of the scatterers. Thus, not only the structure but also the dynamics of the particle system can be examined by light scattering. The physical mechanism responsible for the fluctuations can be described as a Doppler effect. The Doppler shifts cause a broadened spectrum in the frequency domain which is equivalent to a fluctuating electric field in the time domain.
